Abstract

The current paper presents mathematical programming models for use in benchmarking where multiple performance measures are needed to examine the performance and productivity changes. The standard data envelopment analysis method is extended to incorporate benchmarks through (i) a variable-benchmark model where a unit under benchmarking selects a portion of benchmarks such that the performance is characterized in the most favorable light, and (ii) a fixed-benchmark model where a unit is benchmarked against a fixed set of benchmarks. The models are applied to a large Canadian bank where some branches’ services are automated to reduce costs and increase the service speed, and ultimately to improve productivity. The empirical investigation indicates that although the performance appears to be improved at the beginning, productivity gain has not been discovered. Our finding can facilitate the bank in examining its business options and further point to weaknesses and strengths in branch operations.

1. Introduction

Performance evaluation and benchmarking has become an important continuous improvement tools for business units in the high-technology world of computers and telecommunications where competition is intense and grows more so each day. Benchmarking activities positively force any business unit to constantly evolve and improve in order to survive and prosper in a business environment facing global competition. In fact, as reported in a recent Wall Street Journal poll \textsuperscript{[1]}, benchmarking is one of the top three important and popular tools for continuous improvement. Gap analysis is often used as a fundamental method in performance evaluation and benchmarking. However, as pointed out by Camp \textsuperscript{[2]}, one of the dilemmas that we face is how to show benchmarks where multiple measurements exist. It is rare that one single measure can suffice for the purpose of performance evaluation. As a result, some multi-factor based gap analysis methods have been developed, e.g., Spider charts, AHP maturity index, and Z charts. Although gaps can be identified within each performance measure, it remains a challenging task to combine the multiple measures in the final stage.

Therefore, benchmarking models that can deal with multiple performance measures and provide an integrated benchmarking measure are needed. Note that a mathematical programming based method—data envelopment analysis (DEA) \textsuperscript{[9]} has been proven an effective tool for evaluating the relative efficiency of peer decision making units (DMUs) when multiple performance measures are present. DEA evaluates efficiency without the need to specify the relationships or tradeoffs among the performance

measures prior to the computation, and DEA identifies an efficient frontier (tradeoff curve) along with efficiency scores for all DMUs. This type of efficiency evaluation has also been regarded as benchmarking [3], since the efficient frontier identified can be regarded as an empirical benchmark frontier. However, when a new DMU outperforms the identified efficient frontier, a new frontier is generated by DEA. As a result, we do not have the same benchmark for other new DMUs, i.e., the original DEA method cannot be viewed as a multi-criteria performance benchmarking tool.

Zhu [18] developed two DEA-based benchmarking models where the identified efficient frontier (benchmark) remains the same during the benchmarking process. One is called variable-benchmark model where each DMU under benchmarking is allowed to choose a portion of benchmark frontier so that the benchmarking performance of the DMU is characterized in the most favorable light. The other is called fixed-benchmark model where each DMU is benchmarked against fixed components from the benchmark frontier. The current study applies the two DEA-based benchmarking models to a large Canadian bank (thereafter, CBANK) in measuring the effectiveness service delivery benchmarking models to a large Canadian bank (thereafter, CBANK) in measuring the effectiveness service delivery frontier. The current study applies the two DEA-based benchmarking models to a large Canadian bank (thereafter, CBANK) in measuring the effectiveness service delivery.

There are many DEA studies on banking performance. For example, Sherman and Gold [4] published the first significant DEA bank analysis and started what turned out to be a long list of DEA applications to banking from several different angles [5]. Sherman and Ladino [6] reported that a number of DEA studies on banking performance. For example, Sherman and Gold [4] published the first significant DEA bank analysis and started what turned out to be a long list of DEA applications to banking from several different angles [5]. Sherman and Ladino [6] reported that a number of DEA applications to banking from several different angles [5].

The rest of the paper is organized as follows. The next section introduces some basic DEA models. We then introduce our DEA-based benchmarking models described in Zhu [18]. The models are applied to benchmark a set of e-branches against the best-practice of traditional branches. Concluding remarks are given at last.

2. DEA models

We assume that there are $n$ DMUs. In the current paper, the DMUs represent bank branches. Each DMU, $j = 1, 2, \ldots, n$, consumes a vector of inputs, $x_j = (x_{j1}, x_{j2}, \ldots, x_{jm})$, to produce a vector of outputs, $y_j = (y_{j1}, y_{j2}, \ldots, y_{js})$. The relative efficiency of DMU$_{j0}$, among others, can be measured by the following DEA model:

$$\min \theta_{j0}$$

s.t. $\sum_{j=1}^{n} \lambda_j x_{ij} \leq \theta_{j0} x_{j0}$, $i = 1, 2, \ldots, m,$

$$\sum_{j=1}^{n} \lambda_j y_{rj} \geq y_{rj0}, \quad r = 1, 2, \ldots, s,$$

$$\lambda_j \geq 0.$$

(1)

The dual program to model (1) is

$$\max \sum_{r=1}^{s} u_r y_{rj0}$$

s.t. $\sum_{r=1}^{s} u_r y_{rj} - \sum_{i=1}^{m} v_i x_{ij} \leq 0$, $j = 1, \ldots, n,$

$$\sum_{i=1}^{m} v_i x_{j0} = 1,$$

$$v_i \geq 0, \quad u_r \geq 0.$$  

(2)

To refine the results obtained from model (1) or (2), value judgment in forms of weight restrictions can be incorporated into model (2).

$$A_r \leq \frac{u_r}{u_{r0}} \leq B_r,$$

$$C_i \leq \frac{v_i}{v_{i0}} \leq D_i,$$

(3)

where $A_r, B_r, C_i, D_i$ are pre-specified constants. Model (3) is called assurance region in [8] and is closely related to the cone ratio concept of Charnes et al. [10].

When the optimal value to model (1) or (2) is equal to one, we say that a specific DMU under evaluation is a best-practice DMU. Model (1) or (2) assumes that the best-practice frontier exhibits constant returns to scale (CRS). i.e., a best-practice DMU is both technically and scale efficient. If scale inefficiency is allowed in best-practice DMUs, we can assume variable returns to scale (VRS) and incorporate $\sum_{j=1}^{n} \lambda_j = 1$ into model (1). (For a complete discussion on standard DEA models, please refer to [11].)

Benchmarking is a process of defining valid measures of performance comparison among peer units, using them to determine the relative positions of the peer units, and ultimately, establishing a standard of excellence. Through the use of DEA, we can establish a “standard of excellence” via best-practice identification. Once we have the “standard
