## Abstract

**Background:** Hamstring muscle strain injury (hamstring injury) due to excessive muscle strain is one of the most common injuries in sports. The relationships among hamstring muscle optimal lengths and hamstring flexibility and strength were unknown, which limited our understanding of risk factors for hamstring injury. This study was aimed at examining the relationships among hamstring muscle optimal lengths and flexibility and strength.

**Methods:** Hamstring flexibility and isokinetic strength data and three-dimensional (3D) kinematic data for hamstring isokinetic tests were collected for 11 male and 10 female recreational athletes. The maximal hamstring muscle forces, optimal lengths, and muscle lengths in standing were determined for each participant.

**Results:** Hamstring muscle optimal lengths were significantly correlated to hamstring flexibility score and gender, but not to hamstring strength. The greater the flexibility score, the longer the hamstring muscle optimal length. With the same flexibility score, females tend to have shorter hamstring optimal muscle lengths compared to males. Hamstring flexibility score and hamstring strength were not correlated. Hamstring muscle optimal lengths were longer than but not significantly correlated to corresponding hamstring muscle lengths in standing.

**Conclusion:** Hamstring flexibility may affect hamstring muscle maximum strain in movements. With similar hamstring flexibility, hamstring muscle maximal strain in a given movement may be different between genders. Hamstring muscle lengths in standing should not be used as an approximation of their optimal lengths in calculation of hamstring muscle strain in musculoskeletal system modeling.

## 1. Introduction

Hamstring muscle strain injury (hamstring injury) is one of the most common injuries in track and field, soccer, Australian football, rugby, and American football involving high-speed running, jumping, and kicking, accounting for up to 29% of all injuries in these sports.<sup>1,2</sup> Although most hamstring injuries do not require surgical treatment, athletes typically need 2 to 8 weeks to recover from the injuries and get back to their preinjury level of activity,<sup>3–6</sup> which results in substantial time and financial losses.<sup>7–9</sup> Athletes who sustained hamstring injuries have a high reinjury rate of 12%–31%.<sup>10–11</sup> Reinjured ham-

strings take an even longer time to recover.<sup>12</sup> Repeated hamstring injury may result in longer rehabilitations, chronic pain, disability, and even the end of an athletic career.<sup>13</sup> Because of the significant financial and time loss and significant consequences of hamstring injuries, intensive efforts have been made to prevent hamstring injuries and improve rehabilitation in the past 3 decades. A recent extensive review of literature with detailed injury rates, however, revealed that injury and reinjury rates remained unchanged,<sup>14</sup> which indicate a need for further studies on hamstring injury prevention and rehabilitation.

To effectively prevent and rehabilitate hamstring injury, identifying risk factors for the injury is critical. Flexibility and strength are 2 proposed risk factors for hamstring injury. However, the results of clinical studies on the effects of hamstring flexibility and strength on the risk of hamstring injury are inconsistent. Several studies showed that the risk of hamstring injury negatively correlated to hamstring flexibility,<sup>15–17</sup>

69 whereas other studies showed no correlation.<sup>18–20</sup> In  
70 addition, studies showed that the risk of hamstring injury  
71 negatively correlated to the ratio of hamstring to quadriceps  
72 muscle strength,<sup>19,21,22</sup> whereas other studies showed no  
73 correlation.<sup>16,23,24</sup>

74 Several studies using animal models demonstrated that a  
75 muscle strain injury occurs when the muscle is stretched or  
76 during an eccentric contraction, and active muscle strain  
77 reaches a certain magnitude regardless of muscle force and  
78 strain rate.<sup>25–30</sup> These results suggest that the direct cause of  
79 muscle strain injury is muscle strain instead of muscle force and  
80 strain rate. Like other materials, muscle strain is defined as the  
81 ratio of muscle length deformation to muscle resting length,  
82 which itself is defined as the maximum muscle length at which  
83 the parallel elements are not generating force.<sup>31</sup> Muscle resting  
84 length can be approximated as the muscle optimal length,  
85 which is defined as the muscle length at which the force gener-  
86 ated by muscle contractile elements is maximal.<sup>32,33</sup> The  
87 greater the hamstring optimal lengths, the lower the maximal  
88 hamstring muscle strains in a given athletic task with similar  
89 range of lower extremity motion.

90 Hamstring flexibility and strength should be correlated to  
91 hamstring optimal lengths if they are risk factors for hamstring  
92 injury. However, the relationships of hamstring muscle optimal  
93 lengths with hamstring flexibility and strength are still  
94 unknown. An *in vivo* study that investigated the optimal knee  
95 flexion angle at which isokinetic knee flexion moment was  
96 maximal showed that legs recovered from hamstring injury had  
97 a greater optimal knee flexion angle in comparison to legs  
98 without the injury for the same athletes.<sup>34</sup> This result indicates  
99 that legs with hamstring injury may have shorter muscle  
100 optimal length in comparison to legs without injury. Alonso  
101 et al.<sup>35</sup> reported that the mean optimal knee flexion angles were  
102 75° for legs with tight hamstring muscle and 65° for legs with  
103 more flexible hamstring muscles. Other studies showed that 6 to  
104 8 weeks of stretching training improved hamstring flexibility  
105 and decreased optimal knee flexion angle by 4° to 10°.<sup>36,37</sup>  
106 These results indicate that hamstring muscle optimal lengths  
107 may be correlated to hamstring flexibility. However, the rela-  
108 tionships of hamstring muscle optimal lengths with flexibility  
109 have not been established. Our literature review also did not  
110 reveal any association between hamstring strength and muscle  
111 optimal lengths. Furthermore, several studies indicated that  
112 muscle flexibility and strength were correlated,<sup>38–40</sup> whereas our  
113 literature review revealed that these indications have not been  
114 confirmed. In addition, hamstring muscle lengths in standing  
115 were used as an approximation of hamstring muscle optimal  
116 lengths to estimate hamstring muscle strains in athletic  
117 tasks.<sup>41–43</sup> Obtaining hamstring muscle length in standing is  
118 easier than obtaining hamstring muscle optimal lengths.  
119 However, the relationships of hamstring muscle lengths in  
120 standing with their optimal lengths are still unknown.

121 The purpose of this study was to determine the relationships  
122 among hamstring muscle optimal length, flexibility, and  
123 strength, and the relationship between hamstring muscle  
124 optimal length and hamstring muscle length in standing. We  
125 hypothesized that hamstring muscle optimal length would be

Fig. 1. Passive straight leg raise (PSLR) test and hip flexion angle.

128 positively correlated to hamstring flexibility and strength. We  
129 also hypothesized that hamstring strength and flexibility would  
130 be significantly correlated. In addition, we hypothesized that  
131 hamstring muscle optimal length would be significantly differ-  
132 ent from but significantly correlated to hamstring muscle length  
133 in standing.

## 2. Materials and methods

### 2.1. Participants

134 Twenty-one college students (11 males and 10 females)  
135 regularly participating in exercise and sport activities volun-  
136 teered to participate in this study and all participants gave  
137 written consent. The means of ages, standing heights,  
138 and body masses were  $24.7 \pm 2.9$  years,  $174.0 \pm 3.1$  cm,  
139 and  $65.6 \pm 5.9$  kg, respectively, for male participants, and  
140  $23.6 \pm 0.9$  years,  $163.8 \pm 3.8$  cm, and  $53.5 \pm 4.4$  kg, respec-  
141 tively, for female participants. All participants had no history of  
142 hamstring injury or other lower extremity injuries that pre-  
143 vented them from performing the tasks in this study. The use of  
144 human subjects was approved by the Institutional Review  
145 Board of Beijing Sport University.

### 2.2. Protocol

146 Each participant had a 5- to 10-min warmup including  
147 jogging and stretching, then underwent a passive straight leg  
148 raise (PSLR) test<sup>44</sup> (Fig. 1) to evaluate hamstring flexibility and  
149 an isokinetic strength test to determine hamstring muscle  
150 optimal length for each leg. Each participant had three PSLR  
151 trials for each leg. The body position in maximum hip flexion  
152 angle in each PSLR trial was recorded. In the hamstring  
153 isokinetic strength test, retroreflective markers were placed  
154 bilaterally at the anterior superior iliac spine (ASIS), the top of  
155 the crista iliaca, the greater trochanter, the lateral and medial  
156 femur condyles, the lateral and medial malleolus, the tibial  
157 tuberosity, and the center of the second and third metatarsals.  
158 An additional marker was placed on the L4-L5 interface. The  
159 participant performed a calibration trial in a standing position,  
160 then the marker on L4-L5 was removed. The participant was
